Abstract
LiNiO₂ was examined as cathode materials for the lithium-ion battery, working with non-flammable electrolyte, obtained by dissolution of solid lithium bis(trifluoromethanesulphonyl)imide (LiNTf₂), lithium bis(oxalato)borate (LiBOB) and lithium hexa fluorophosphate (LiPF₆, Fluka) in sulfolane (TMS) with 10% vinylene carbonate (VC). The Li/LiNiO₂ cells were tested by cyclic voltammetry, galvanostatic charging/discharging. The LiNiO₂ cathode showed good cyclability and coulombic efficiency for the electrolyte, which contains 1 M LiPF₆ in TMS+10%VC (195 and 140 mAhg⁻¹ after 20 cycles-C/10). Correspondingly lower capacity was observed for system Li/LiNiO₂ in: 1 M LiNTf₂ in TMS+10%VC and 1 M LiBOB in TMS+10%VC. The LiNiO₂ (solid)+1 M LiPF₆+TMS+10%VC system show a flash point of ca. 160°C (classical LiNiO₂+1 M LiPF₆+EC 50%+DMC 50% system: Tₖ ≈ 42°C).

Keywords: Sulfolane; Li-ion battery; Cathodes; LiNiO₂; Impedance spectra

Introduction
Lithium ion batteries (LIBs) have become the most prominent choice of power source for all types of portable microelectronic devices, as they offer higher energy density than the other rechargeable power sources [1,2]. Development of a highly efficient, thin film positive electrode which can provide high cell voltage, high specific capacity and cycling stability even at rapid charge/discharge rates, is the key issue of electrochemical research [3,4]. Good Enough et al. was the first to report a layered lithium cobalt oxide (LiCoO₂) positive electrode material in the 1980’s. In the practice major limitation is connected with the removal of Li from LixCoO₂ i.e., de lithiation of LiCoO₂ restricted to x ≤ 0.5, which corresponds to 4.2 V vs. Li/Li (a capacity value of 140 mAhg⁻¹). However, several efforts have been expended to extract extra capacity and to cycle the LiCoO₂ cathode beyond 4.2 V so as to increase energy density of the LIB’s [2-17]. This would be connected with obtain: desirable properties of LiCoO₂ as a cathode without post deposition heat treatments at elevated temperatures [7,9], replacing a part of base transition metal (Co) with another element (Ni, Mn, Ti, Fe etc.) [10,11], surface modification of LiCoO₂ films with inert metal oxides (MOₓ, M = Al, Mg, Sn, Zn, Zr) and inorganic salts (AlF₃, Al(OH)₃, AlPO₄) [12] and development of various nano-structured LiCoO₂ materials [13-16] and tailoring the morphological properties [17,18].

LiNiO₂ is known to be difficult to synthesize and its multi-phase reactions during electrochemical cycling lead to structural degradation [19-30]. During the charge process, LiNiO₂ undergoes a sequential change in its crystal structure from the hexagonal phase to the monoclinic phase, to the hexagonal phase again, followed by two hexagonal phases, and finally a single hexagonal phase [31]. There are also concerns over the thermal stability of LiNiO₂ in the charged state. To overcome the difficulties with its synthesis and structural instability during cycling and to improve thermal safety, the nickel ion has been substituted by various metal ions (e.g., Mg, Al, Mn, Ga) [32-35]. It has been reported that the substitution process stabilizes the crystal structure of the material during the intercalation/deintercalation of lithium ions, even in an overcharged state, and there by improves LiNiO₂ cycle ability. A molten-salt method has been found to be a simple means to prepare pure and stoichiometric powders of multi-component oxides, in which the molten salts are utilized as solvent or reacting species [36,37]. Since the diffusion rates of the components in molten salts are much higher than those in a solid-state reaction, various powders, such as LiCoO₂, can

be prepared at significantly lower temperatures [38]. Han et al. [38,39] investigated the preparation of LiCoO₂ and LiCoₐₓMₜₓO₂ (M=Al, Ni) by molten-salt synthesis.

The general aim of this study was to investigate a new electrolyte: 1 M LiPF₆ in TMS+10%VC; 1 M LiNTf₂ in TMS+10%VC and 1 M LiBOB in TMS+10%VC working in both systems Li/LiCoO₂ and Li/LiNiO₂.

**Experimental**

**Materials**

Graphite, (G, SL-20, BET surface area 6.0 m²g⁻¹, Superior Graphite, USA), carbon black, (CB, Fluka), poly(vinylidene fluoride) (PVdF, Fluka), sulfolane (TMS, Fluka), lithium foil (Aldrich, 0.75 mm thick), vinylene carbonate (VC, Aldrich), N-methyl-2-pyrrolidinone (NMP, Fluka), lithium bis(trifluoro methane sulfonyl)imide (LiNTf₂, Fluka), lithium hexa fluorophosphate (LiPF₆, Fluka), lithium bis(oxalato)borate (LiBOB Fluka), LiNiO₂ powder (Aldrich) were used as purchased. Electrolytes were obtained by dissolution of the solid LiPF₆, LiNTf₂, and LiBOB salts in liquid TMS heated to ca. 35°C (TMS is solid at room temperature). Electrolytes contained VC as a SEI forming additive (10%). Tested LiNiO₂ and LiCoO₂ cathodes were prepared by casting LiNiO₂/LiCoO₂+G+ PVdF (ratio 85:5:10) slurry in N-methyl-2-pyrrolidinone (NMP, Fluka) on the current collector (diameter 12 mm) (NMP was evaporated in vacuum at 120°C).

**Apparatus and measurements**

Particle size distributions were determined for LiNiO₂. Measurements were performed on a Zeta sizer Nano ZS made by Malvern Instruments Ltd. UK, using the non-invasive back scattering method (NIBS). From the particle size distribution the polydispersity index was calculated, which provides information on the homogeneity of the product particles. The morphology and microstructure of the products were examined using a scanning electron microscope (Zeiss EVO40). From these images it was also possible to determine the particle structures and their tendency towards aggregation or agglomeration.

The performances of the cells were characterized using galvanostatic charge-discharge tests. Cycling efficiency of LiNiO₂/G, LiNiO₂/G, LiNiO₂/G systems was measured in two compartment cells. Electrodes were separated by the glass microfiber GF/A separator (Whatman), placed in an adopted 0.5 Swagelok® connecting tube. Typically, the mass of electrodes was as follows: Li: ca. 45 mg (0.785 cm²) and cathode: 2.0-3.0 mg, graphite: 3.0-4.0 mg. The cells were assembled in a glove box in the dry argon atmosphere. The cycling measurements were taken with the use of the ATLAS 0461 MBI multichannel electrochemical system (Atlas-Sollich, Poland) at different current rates (C/10-C/2). Cyclic voltammetry (CV) and ac impedance measurements were performed using the μAutolab FRA2 type III electrochemical system (Ecochemie, Netherlands).

Thermal gravimetric analysis was conducted with the use of the STA 449 F3 Jupiter TG/DTA analyser (NETZSCH-Gerätebau GmbH) with the 2°C min⁻¹ rate. Flash point of the electrolyte was measured with an open cup home-made apparatus, based on the Cleveland open cup instrument, with a 1.5 ml cup. The cup was heated electrically through a sand bath, and temperature was measured with the M-3850 (Metex, Korea) digital thermometer. The apparatus was scaled with a number of compounds of known flash points.

**Results**

**PSD and morphology**

Figure 1 shows particle size distributions and SEM images of LiNiO₂ (a, b) and LiCoO₂ (c, d) respectively. LiNiO₂ is characterised

![Figure 1](https://example.com/figure1.png)
by a mono modal particle size distribution with diameters in the range 825–1720 nm (Figure 1a). As evidenced by the SEM image (Figure 1b) the particles are regular in shape. The cathode is highly homogeneous, as is confirmed by the low polydispersity index of 0.326. Average particle diameter is lower than for LiCoO₂, amounting to 1050 nm. 

**Electrolyte liquidity range, viscosity and conductivity**

Sulfolane is a five-membered heterocyclic sulfur-organic compound containing a sulfonyl functional group. This group is composed of a sulfur atom connected by double bonds with two oxygen atoms. The sulfur-oxygen double bond is highly polar, ensuring the miscibility of sulfolane with water, while the carbon backbone affects good solubility in hydrocarbons, whereby sulfolane is widely used as a solvent for the purification of hydrocarbon mixtures.

Melting point of sulfolane is relatively high (301.6 K (ca. 28°C)) [40] and hence, it is solid at room temperature. Consequently, melting point of ca. 1 M solutions is lower by ca. 60 K in comparison to that of pure sulfolane (240 K (ca.-33°C)) which is sufficient from the practical point of view. Due to their high boiling point and cryoscopic constant, solutions in sulfolane are characterized by a broad liquidity range (ca. 300 K). Conductivity of the electrolyte at T=298 K is 2.6 mS cm⁻¹, with the activation energy of the conduction process, \(E_a\) = 18.4 kJ mol⁻¹ [41,42]. Viscosity, \(\eta\), of sulfolane is relatively high and strongly depends on temperature. Sulfolane viscosity, near its melting point is relatively high (ca. 10 cP at 30°C) [40].

**Charging/discharging**

LiNiO₂: Literature sources contain much information on the obtained capacity for the discussed cathode. LiNiO₂ exists in two structural modifications, of which only one is electrochemically active [43]. The theoretical capacity of LiNiO₂, assuming 1 Li per NiO₂ unit may be extracted, is close to that of the LiCoO₂ compound, i.e., ~ 275 mAh g⁻¹. Again, in a similar fashion to the cobalt system, a significantly lower capacity is obtained in actual test cells. However, the overall reversible specific capacities reported for LiNiO₂ are typically 10-30 mAh g⁻¹ higher than those of LiCoO₂. Fewer cycles have been reported, but good charge retention is generally observed after >100 cycles. The very small particle size was claimed to be advantageous in one report, but unfortunately no electrochemical data were presented. The cycle life size is strongly dependent on the depth of discharge [44], i.e., high cycle numbers are obtained when the capacity is restricted to about 100-120 mAh g⁻¹, while only a few cycles are possible at higher capacities. In addition, the LiNiO₂ compound appears to be more difficult to synthesize than the corresponding cobalt oxide, in a modification which is able to reversibly insert lithium to any significant extent. In contrast to LiCoO₂, which can be prepared by sintering a mixture of almost any Li, Co and O sources under proper temperature conditions, the LiNiO₂ compound needs to be prepared under strongly oxidizing conditions. Typical examples include e.g., hydroxide mixtures annealed in an O₂ atmosphere, hydroxide and nitrate or by the use of Na₂O₂ and a Ni source, followed by ion exchange with LiNO₃ at an elevated temperature.

The structure of LiNiO₂ is described in previous text [45-48], while the structure of Li₂NiO₃ is also discussed in previous text [46]. The latter paper also discusses lithium insertion in the approximate range 1<x<2 in Li₂NiO₃, which takes place at about 1.8 V versus Li. This is in contrast to lithium insertion in LiCoO₂, where no plateau around this voltage is found [46]. The solid state ionic transport properties of LiNiO₂ are discussed in previous text [49] while other physical/chemical properties are given in a number of references [50-52]. Performance results, comparable to those of liquid electrolyte systems, were obtained with Li/LiNiO₂, Li/LiMn₂O₄/C, LiNiO₂ and C/LiCoO₂ cells [53], using a PAN based hybrid polymer electrolyte (i.e., polymer-liquid-salt combination, [54]) at room temperature. However, a rapid decay of the capacity with cycling was observed in the early experiments with the carbon anode based systems [55-68]. The half-cells was tested for 50 cycles, but Figures 2-4 present charging/discharging for the first 20 cycles.

**Figures 2-4** show charge-discharge curves and coulombic efficiency of the Li/LiNiO₂ half-cell using: 1 M LiPF₆ in TMS+10%VC (Figure 2) 1 M LiNTf₂ in TMS+10%VC (Figure 3) and 1 M LiBOB in TMS+10%VC (Figure 4).

![Figure 2](image1.png)

**Figure 2** Charging capacity a) Discharging capacity b) Coulombic efficiency c) of the cell: LiNiO₂|1 M LiPF₆ in TMS+10%VC | Li (rates: C/10, C/7, C/5, C/2).
The highest capacity is observed for the system Li [1 M LiPF₆ in TMS+10%VC] LiNiO₂. The capacity of the charging (deintercalation) and discharging (intercalation) processes after 20 cycles was 200 mAhg⁻¹ and 195 mAhg⁻¹, resulting in a coulombic efficiency of 98% under the current rate C/10. Moreover when the current is increased from C/10 to C/2 charge and discharge capacity decreases after 20 cycles to 144 mAhg⁻¹ and 135 mAhg⁻¹, respectively (Figure 2) the reversible capacity is not low and accounts for 70% of the theoretical value, which is a good result with promising prospects for further research. Slightly worse properties of the LiNiO₂ cathode are observed for other electrolytes. The charging/discharging capacity for Li [1 M LiNTf₂ in TMS+10%VC] LiNiO₂ is found within a range of 180-170 mAhg⁻¹ and 170-162 mAhg⁻¹ resulting in a coulombic efficiency of 95% (current is increased than charge and discharge capacity decreased)(Figure 3).

The lowest coulombic efficiency, of about 90%, is observed for the system Li [1 M LiBOB in TMS+10%VC] LiNiO₂. The electrolyte containing LiBOB was the least stable during the charging/discharging process (Figure 4).

Electrolyte flammability

In lithium-ion cells containing classical electrolytes the solvent may start to evaporate and consequently, the vapour may ignite. Therefore, for safety reasons, it is of practical significance to look for new non-volatile electrolytes. Many ionic liquids, due to the strong ion–ion interactions, are characterized by negligible vapour pressure at room temperature. On the other hand, the SEI forming additives, such as VC, are volatile organic compounds and it is necessary to estimate the flash point of such mixtures (Figure 5).

Flash points of ethylene carbonate and propylene carbonate are 143°C and 123°C, respectively (Sigma-Aldrich and Merck catalogues), while in the case of dimethyl carbonate it is only 16°C (Sigma-Aldrich catalogue). Flash point of neat sulfolane is much higher than 177°C [40]. In addition, if the electrolyte in cyclic carbonates is in contact with the cathode, the flash point may be reduced. The system under study: i.e., LiNiO₂ (solid)+1 M LiPF₆+TMS+10%VC have a flash point of ca. 160°C. This is much higher in comparison to that characteristic of a classical LiNiO₂(solid)+1 M LiPF₆+EC 50%+DMC 50% system (T_f=42°C).
During SEI formation the volatile additive (VC) is converted into a solid polymeric component of the interface. Consequently, the amount of the volatile compound decreases to a low value, increasing the flash point of the electrolyte. The flash point determined for the: LiPF$_6$ solution in TMS, without VC, is 168°C, LiNTf$_2$ solution in TMS, without VC, is 155°C and LiPF$_6$ solution in TMS, without VC, is 153°C.

Figure 6 shows thermal gravimetric analysis (TG/DTA) of the 1 M LiPF$_6$+TMS+10%VC electrolyte under nitrogen atmosphere. It can be seen that the main decomposition peak of the electrolyte (both liquid solvents and the lithium salt) is found at ca.275°C. The TG/DTA profiles shown in Figure 6 are similar to those found to poly vinylidene fluoride-based gel electrolyte [42].

No significant differences were observed in the TG/DTA for other electrolytes (1 M LiNTf$_2$+TMS+10%VC or 1 M LiBOB+TMS+10%VC). The peak appears at approximately 260°C-280°C (Figures 7 and 8).

Cyclic voltammetry
A cyclic voltammogram of the Pt [1 M LiPF$_6$ in TMS+10%VC] system is given in literature [68]. Cyclic voltammograms of the graphite electrode in 1 M LiNTf$_2$ dissolved in TMS is shown in Figure 9a Examination of the curve of the first cycle (the first reduction process) shows two fine peaks around 0.2 and 0.7 V, presumably corresponding to the formation of SEI on the surface anode. These peaks which disappear completely with further cycling are apparently due to VC reductions. The next stage of lithium intercalation occurs at potential below 0.3 V and reaches a peak at a potential 0.005 V. The difference between the CV curve of the first cycle and subsequent cycles indicates that the irreversible capacity mainly occurs in the first cycle. A similar
picture is observed in the case of the second electrolyte, i.e., 1 M LiBOB dissolved in TMS (Figure 9b).

**Impedance studies**

For a system containing lithium salt: LiNTf₂ in TMS was decided to perform a comparative study by performing temperature impedance spectrum. Figures 10a and 10b have impedance spectra of C₆Li|LiNTf₂ in TMS |Li and LiNiO₂|LiNTf₂ in TMS|Li cells. Spectra were deconvoluted according to the equivalent circuit shown in Figure 10c. The conductivity of 1.0 M LiNTf₂ in TMS at 25°C was 2.6 mS cm⁻¹, with the activation energy of the conduction process $E_a$=18.4 kJ mol⁻¹. Therefore, the specific conductivity of the electrolyte at 90°C was 9.8 mS cm⁻¹, which is comparable to the corresponding value characteristic of classical solutions in cyclic carbonates working at room temperature. Corresponding resistance of the electrolyte in cells, $R_{cell}$ was somewhat higher than that expected from its conductance, due to the porous structure of both electrodes. However, at 90°C it decreased considerably to ca. 8 Ω.

The resistance of the SEI layer, $R_{SEI}$ formed at 25°C on the graphite anode and the LiNiO₂ cathode was ca. 9 Ω and 51 Ω, respectively. The corresponding value for SEI formed at 90°C, was higher, achieving 32 Ω (C₆Li) and 67 Ω (LiNiO₂). A possible explanation is that at a higher temperature the thickness of the formed SEI layer was higher.

The corresponding charge transfer resistance for the LiNiO₂|Li⁺ cathode (ca. 2.80 mg, BET specific area 15.4 m² g⁻¹, real surface area A=431 cm²) was lower: ca. 5.96 × 10⁻⁵ A cm⁻² and 7.26 × 10⁻⁵ A cm⁻² at 25°C and 90°C, respectively.

The line at the low-frequency region is due to the diffusion of the electro-active species. Generally, any software system used for EIS curve deconvolution applies the Warburg model, which is based on a symmetrical constant phase element. Hence, the diffusion process was approximated here also by the Warburg element $Z_{w}$. Slopes of linear parts of impedance spectra were not exactly 45°C as predicted by the Warburg model. Moreover, in the case of the C₆Li|Li⁺ anode, the diffusion impedance increases with an increasing temperature which is difficult to explain. However, the LiNiO₂ cathode diffusion impedance decreases considerably with the temperature increase. Numerical evaluation of the diffusion coefficient of Li in the graphite anode or the LiNiO₂ cathode is impossible as the concentrations of diffusing species in the solid state have been unknown.

**Conclusion**

The solvent used to lower flammability - sulfolane, has a high melting point of 27.5°C. Sulfolane would greatly limit the range of temperatures where it can be used. For these reason we need to add lithium salts, which modify mixture facilitating better use in li-ion batteries. The study tested the addition of salts (LiPF₆, LiNTf₂ and LiBOB) to sulfolane and efficiency for each cell cathodes (LiNiO₂ and LiCoO₂).
1. These results show that sulfolane with an addition of LiPF$_6$, LiNTf$_2$ and LiBOB can be a good electrolyte for application in Li-ion batteries using cathode: LiNiO$_2$. Charging/discharging capacity was stable and occurs between 200-180 mAhg$^{-1}$ for LiNiO$_2$|Li system. The value depends on the current rate. Coulombic efficiency was 90-95%.

2. Moreover these electrolytes: 1 M LiPF$_6$ in TMS+10%VC; 1 M LiNTf$_2$ in TMS+10%VC and 1 M LiBOB in TMS+10%VC have good cathodic stability and flash points above 160°C.

3. It can be seen from the thermal gravimetric analysis (TG/DTA) of the electrolytes under nitrogen atmosphere that the main decomposition peak of the electrolyte (both liquid solvents and the lithium salt) is present at ca. 275°C.
